**ABSTRACT** Mycobacteria, including pathogens like *Mycobacterium tuberculosis*, exhibit unique growth patterns and cell envelope structures that challenge our understanding of bacterial physiology. This study sheds light on FhaA, a conserved protein in *Mycobacteriales*, revealing its pivotal role in coordinating cell envelope biogenesis and asymmetric growth. The elucidation of the FhaA interactome in living mycobacterial cells reveals its participation in the protein network orchestrating cell envelope biogenesis and cell elongation/division. By manipulating FhaA levels, we uncovered its influence on cell morphology, cell envelope organization, and the localization of peptidoglycan biosynthesis machinery. Notably, *fhaA* deletion disrupted the characteristic asymmetric growth of mycobacteria, highlighting its importance in maintaining this distinctive feature. Our findings position FhaA as a key regulator in a complex protein network, orchestrating the asymmetric distribution and activity of cell envelope biosynthetic machinery. This work not only advances our understanding of mycobacterial growth mechanisms but also identifies FhaA as a potential target for future studies on cell envelope biogenesis and bacterial growth regulation. These insights into the fundamental biology of mycobacteria may pave the way for novel approaches to combat mycobacterial infections addressing the ongoing challenge of diseases like tuberculosis in global health.

**IMPORTANCE** *Mycobacterium tuberculosis*, the bacterium responsible for tuberculosis, remains a global health concern. Unlike most well-studied model bacilli, mycobacteria possess a distinctive and complex cell envelope, as well as an asymmetric polar growth mode. However, the proteins and mechanisms that drive cell asymmetric elongation in these bacteria are still not well understood. This study sheds light on the role of the protein FhaA in this process. Our findings demonstrate that FhaA localizes at the septum and asymmetrically to the poles, with a preference for the fast-growing pole. Furthermore, we showed that FhaA is essential for population heterogeneity and asymmetric polar elongation and plays a role in the precise subcellular localization of the cell wall biosynthesis machinery. Mycobacterial asymmetric elongation results in a physiologically heterogeneous bacterial population which is important for pathogenicity and response to antibiotics, stressing the relevance of identifying new factors involved in these still poorly characterized processes.

tuberculosis ranked as the first cause of death from a single bacterial infectious agent worldwide (1).

One of the peculiarities of this bacillus lies in its cell growth and division modes, which differ significantly from those of well-studied rod-shaped bacteria, such as *Escherichia coli* or *Bacillus subtilis* (2). Mycobacteria need to synthesize a complex cell wall during growth and division. This distinctive structure, composed of peptidoglycan (PG) covalently attached to arabinogalactans esterified with mycolic acids, is relevant for conferring intrinsic antibiotic resistance and plays a major role in host-pathogen interactions and virulence (3, 4). Moreover, unlike model bacilli that incorporate new cell wall material laterally, mycobacteria exhibit an asymmetric polar elongation mode in which the old pole inherited from the mother cell outpaces the newly formed pole in the rate of cell wall synthesis (2, 5). This asymmetric growth pattern contributes to a diversified population in terms of size and antibiotic susceptibility (6). Furthermore, many well-characterized key members of the protein complexes guiding elongation (elongasome) and division (divisome) in *E. coli* and *B. subtilis* are absent among mycobacteria (2, 7). Hence, the molecular mechanisms underlying cell growth and division in these bacteria remain largely unknown. Nevertheless, an increasing number of mycobacterial-specific cell division and elongation protein candidates have started to be identified, including two ForkHead-Associated (FHA) domain-containing proteins, FhaA and FhaB, which specifically recognize phospho-Thr residues (8–10).

FhaA and FhaB are part of a highly conserved operon in *Mycobacteriales*, that also encodes two shape, elongation, division, and sporulation genes (*rodA* and *pbpA*), two Ser/Thr protein kinases (*pknA* and *pknB*), and the unique phosphoserine/threonine protein phosphatase of the genome (11, 12), pointing to its critical role in cell morphology, growth, and its phospho-regulation.

Here, we focused on *M. tuberculosis* FhaA, a still poorly characterized multidomain protein. FhaA presents a C-terminal FHA domain, which specifically recognizes phosphorylated Thr residues, linked by a ~300 amino acid-long unstructured linker to an N-terminal globular domain with no similarity to any known protein (13). Previous reports provide evidence that supports the role of FhaA in the regulation of cell wall biosynthesis through its interaction with two phosphorylated PknB substrates. FhaA was proposed to inhibit the translocation of PG precursors from the cytosol to the periplasm through its interaction with the phosphorylated pseudokinase domain of the Lipid II flippase Mvin (10). It was also shown to interact with phosphorylated CwlM and potentially regulate the biosynthesis of PG precursors (14). In addition, knocking out *fhaA* in *Mycobacterium smegmatis* resulted in a short-cell phenotype (15), while its depletion caused increased accumulation of nascent PG at the poles and septa (10). Some of these previous data are difficult to reconcile, making the roles of FhaA and its molecular mechanisms still unclear.

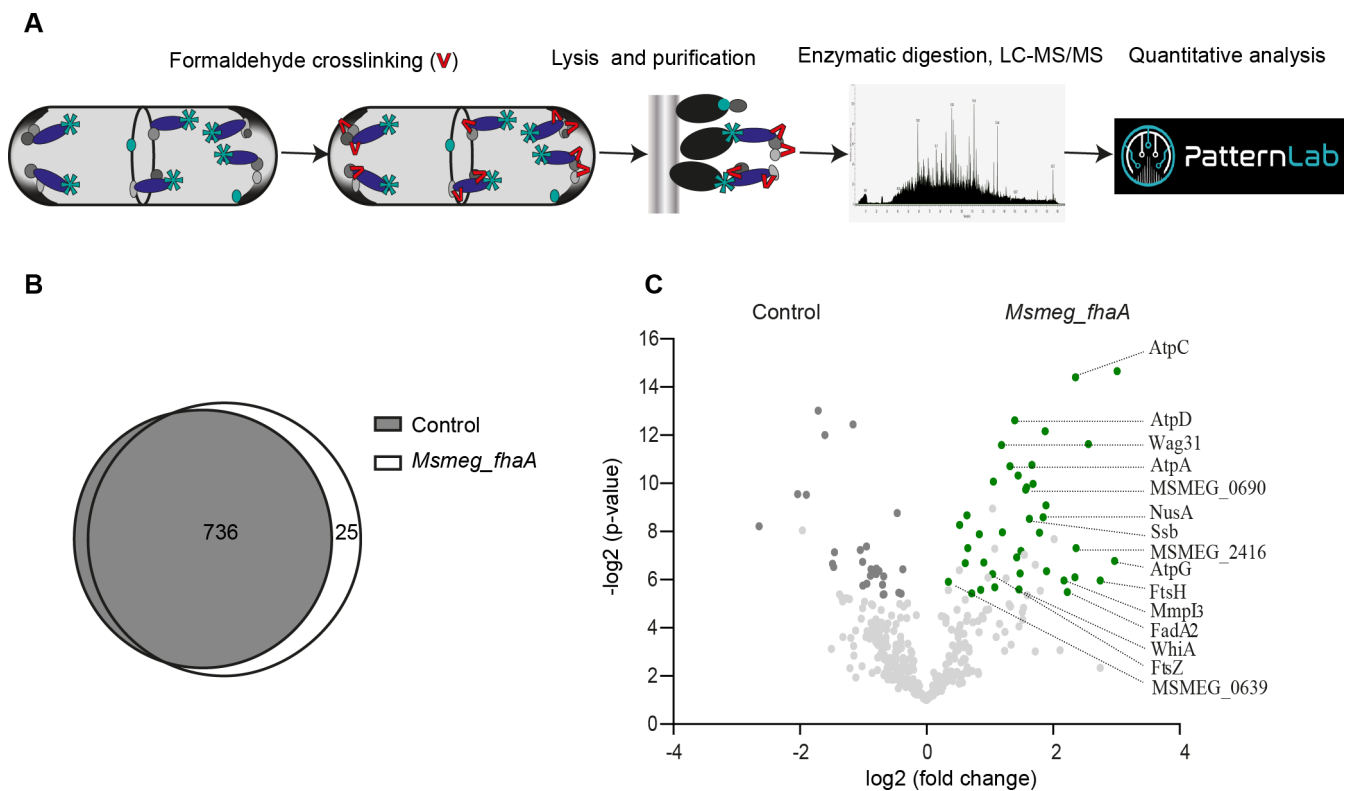

Here, we explored protein-protein interactions involving mycobacterial FhaA in living cells. Our results showed that FhaA is part of an extensive protein network linking cell envelope biogenesis to cell elongation/division in mycobacteria. Overexpressing FhaA in *M. smegmatis* cells leads to alterations in composition and/or organization of the cell envelope along with mislocalization of the PG biosynthesis machinery, whereas the deletion of the *fhaA* gene results in elongation defects and the loss of asymmetrical insertion of new cell wall material at the poles. Collectively, our findings indicate that FhaA plays a crucial role in polar growth by regulating the precise subcellular localization and asymmetric distribution of the cell envelope biosynthetic machinery organized within the elongasome.

## RESULTS

### FhaA interactome in living cells

To decipher the FhaA interactome within live mycobacteria, we employed an unbiased methodology encompassing the overexpression of *M. tuberculosis* Strep-tagged FhaA in *M. smegmatis*. The method relied on a combination of chemical crosslinking, affinity

purification, and protein identification through mass spectrometry (MS) (Fig. 1A). Formaldehyde was selected as the crosslinking agent due to its ability to penetrate the highly hydrophobic cell envelope of mycobacteria and covalently link amino acids in close proximity (16). *M. smegmatis* transformed with the empty plasmid was used as control. To define the FhaA interactome, we compared the proteins recovered by affinity purification in control and *Msmeg\_fhaA* strains, using in five biological replicates per condition. As shown in Fig. 1B, 25 proteins were exclusively detected in at least four replicates of the purified protein complexes from *Msmeg\_fhaA* ( $P \leq 0.01$ ; Table 1). The list includes FhaA itself, Mvin, the flippase previously reported to interact with FhaA (10), and 23 putative direct or indirect FhaA interactors (Table 1; Table S1). In addition, from 736 proteins identified in affinity-purified fractions from both *Msmeg\_fhaA* and control strains, 31 were statistically overrepresented in complexes isolated from *Msmeg\_fhaA* (fold change  $\geq 2$ ; F-stringency: 0.04;  $q$ -value  $\leq 0.05$ ; Fig. 1C; Table S2). Altogether, we report a list of 55 proteins that represent putative direct or indirect FhaA interactors (Table 1; Table S1 and S2). Remarkably, the FhaA interactome comprises proteins with known and predicted physical and functional associations, unveiling statistically enriched compartments, which include the cell pole, cell tip, cell septum, and membrane fraction (Table S3). Among the polar interactors (10, 17–20), two of them (MSMEG\_0317 and MSMEG\_3080) exhibit an asymmetric distribution, specifically targeting the fast-growing pole (Table 1). Furthermore, functional enrichment analysis emphasized various interconnected biological processes, encompassing the regulation

**FIG 1** FhaA interactome in the living cell. (A) Scheme of the strategy used to identify FhaA interacting proteins. Cultures of *M. smegmatis* overexpressing *M. tuberculosis* FhaA fused to Strep-tag were incubated with formaldehyde. FhaA covalently linked to its protein partners was purified using Strep-Tactin columns, and the recovered proteins were digested and identified by nano-liquid chromatography-tandem mass spectrometry (LC-MS/MS). (B) Venn diagram showing the number of proteins identified in *Msmeg\_fhaA* and control strains after affinity chromatography. Using the probability mode of PatternLab Venn diagram module, 25 proteins were statistically identified as exclusive of FhaA interactome ( $P < 0.01$ ; Table 1; Table S1). (C) Volcano plot showing proteins identified in at least 7 replicates of the 10 replicates analyzed, plotted according to its  $P$ -value ( $-\log_2 P$ ) and fold change ( $\log_2$  Fold change). Proteins statistically enriched in FhaA complexes ( $q$ -value  $\leq 0.05$ ) with a fold change greater than 2 are displayed in green, and those related to cell elongation/cell envelope biosynthesis are labeled. Fold changes and  $P$ -values for each of the 31 differential proteins are depicted in Table S2.

<sup>a</sup>Proteins detected in at least four out of five *Msmeg\_fhaA* replicates but absent in all control replicates and statistically validated using the Bayesian model integrated into PatternLab for Proteomics are shown. TMH: transmembrane helix; LAM: lipoarabinomannan; LM: lipomannan. Dashes indicate unknown localization.

of developmental processes, cell shape regulation, as well as cell cycle and division regulation (Table S3). The recovery of previously known interactors, along with proteins that share the same subcellular localization and are involved in the same biological processes as FhaA, points to a reliable and physiologically relevant interactome.

### Proteins recovered from FhaA interactome are related to cell division/elongation and cell envelope biogenesis

A detailed analysis of the FhaA interactors sheds light on its possible functions. The most abundant protein in the FhaA interactome, MSMEG\_0317, is the integral membrane

protein PgfA (for polar growth factor A) that was recently identified as being crucial for growth from the old pole (17). PgfA also interacts with MmpL3, the trehalose monomycolate (TMM) transporter that plays an important role in mycolic acid trafficking across the membrane and cell envelope composition (17, 18). Interestingly, two additional FhaA interactors participate in the regulation of MmpL3-mediated mycolic acid translocation: MSMEG\_5308 and MSMEG\_0736, with the latter being renamed as TtfA (for TMM transport factor A) (18). Overall, the interactome includes nine previously reported MmpL3 interactors (18, 26) in addition to MmpL3 itself.

Proteins that participate in the biosynthesis of the different layers of the complex mycobacterial cell wall were also recovered as FhaA direct/indirect interactors. In addition to Mvin (10), the list includes CwsA (for cell wall synthesis protein A) (27), proteins that participate in lipomannan (LM) and lipoarabinomannan (LAM) biosynthesis such as the polyprenyl monophosphomannose synthase Ppm1 (28, 29) and MSMEG\_0317 (17, 21), or yet the transcriptional regulator WhiA and the DivIVA domain-containing protein SepIVA (MSMEG\_2416), both involved in cell division, cell length, and/or cell envelope biosynthesis (30, 31). Finally, the interactome also includes the scaffolds of the divisome and elongasome machineries (FtsZ and Wag31 respectively). Taken together, these results strongly support the involvement of FhaA in mycobacterial cell envelope biosynthesis during cell growth and division.

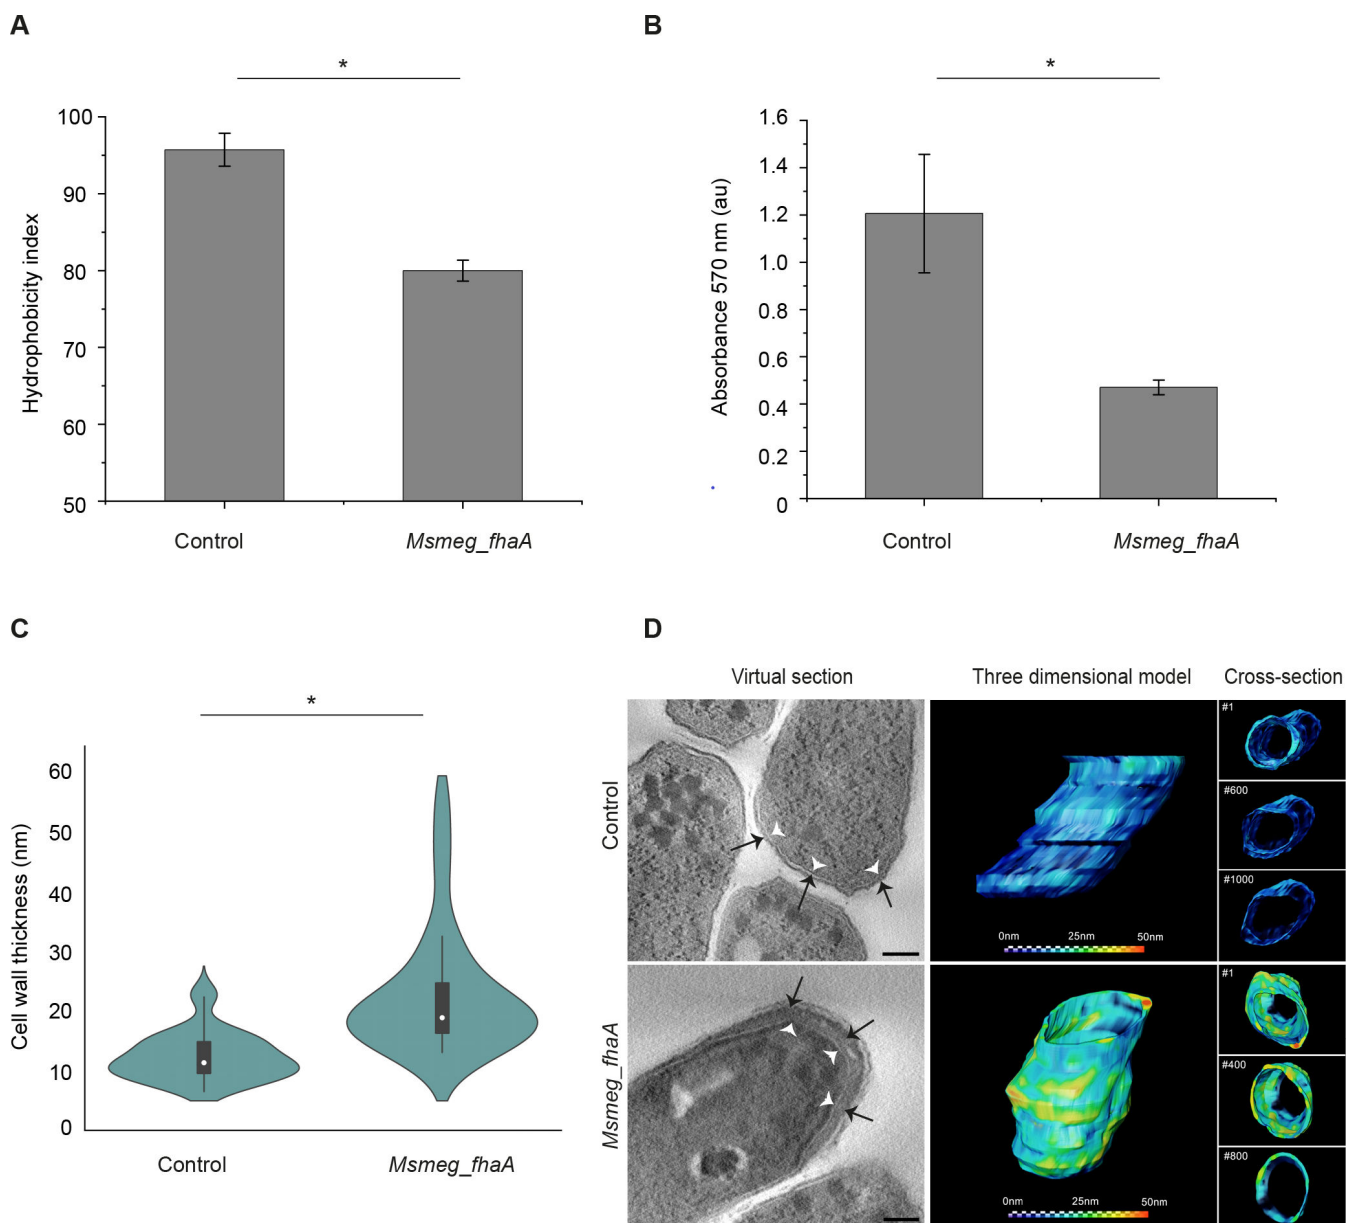

### FhaA overexpression alters cell envelope composition/structure

The overexpression of FhaA leads to a significant decrease in cell surface hydrophobicity (Fig. 2A), supporting the hypothesis that this protein is involved in cell wall biogenesis. As this is a physicochemical property pivotal for cell-cell and cell-surface adhesion behaviors (32, 33), we investigated the impact of FhaA overexpression on the formation of multicellular structures and observed that the *Msmeg\_fhaA* strain has an impaired capability of biofilm formation (Fig. 2B), which is not related to defects in the final biomass reached (Fig. S1A). Furthermore, we confirmed that the strain overexpressing FhaA exhibits altered permeability compared to the control strain. The ethidium bromide uptake assay demonstrated that *Msmeg\_fhaA* is more permeable (Fig. S1B), consistent with our previous results.

Transmission electron microscopy (TEM) images confirmed that the strain overexpressing FhaA exhibits an abnormal cell envelope (Fig. 2C; Fig. S2). The images show areas that have an unusually thick cell wall that appear as electron-lucid blobs with aberrant distribution (Fig. S2). Compared to the control, there is an increase in the average thickness of the cell envelope (Fig. 2C and D), with these thickened areas being heterogeneously distributed across the surface. (Fig. S2). Cell wall maps across the cell volume obtained by electron tomography (ET) further confirm the alterations in the *Msmeg\_fhaA* cell envelope and highlight the thickness heterogeneity along the cell volume (Fig. 2D).

Further evidence for the effect of FhaA overexpression on cell envelope comes from the analysis of membrane properties of the two strains. We used scanning confocal microscopy to image cells previously treated with 6-dodecanoyl-2-dimethylaminonaphthalene (LAURDAN), an amphiphilic fluorescent dye that penetrates the membrane lipids and whose emission spectra change according to environment molecular composition and polarity (34, 35). This approach was previously used to assess cell envelope remodeling in mycobacteria (36, 37). When water accessibility at the membrane interface increases, LAURDAN exhibits a green-shifted fluorescence, while in more ordered membranes, its emission is blue shifted. We used this property to provide an initial, broad assessment of potential differences in the composition and/or physical structure of the lipidic layers and/or its associated cell wall structures, upon FhaA overexpression.

When plotted on a diagram, phasors corresponding to the control strain tend to cluster at higher angles and closer to the origin of the axes compared to those representing *Msmeg\_fhaA* (Fig. 3). In addition, there is a change in the profile on the linear combination obtained at the phasor plot for the two strains. Thus, the misalignment

**FIG 2** FhaA overexpression alters mycobacteria cell surface and cell envelope composition/structure. (A) Cell surface hydrophobicity test. The figure shows the partitioning of control and *Msmeg\_fhaA* strains between phosphate-buffered saline (PBS) and xylene. The graph depicts the hydrophobicity index, defined as the percentage of the initial aqueous layer absorbance retained in the xylene fraction after partitioning. Assays were performed by triplicate mean  $\pm$  SD; \* indicates a statistically significant difference determined by analysis of variance (ANOVA),  $P < 0.05$ . (B) Biofilm formation assay. Biofilm formation was evaluated in 96-well plates, by staining biofilms with crystal violet and measuring absorbance at 570 nm. Mean  $\pm$  SD; \* indicates a statistically significant difference determined by ANOVA,  $P < 0.05$ . (C) Graphic comparison of the average cell wall thickness measured from transmission electron microscopy (TEM) images (Fig. S2) for each strain. Violin plot illustrates the distribution of wall thickness, supporting the heterogeneity observed in the *Msmeg\_fhaA* strain. Kolmogorov-Smirnov was applied;  $n = 30$  cells for each group; \* =  $P < 0.05$ . White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers. (D) Thickness map representing variations in cell wall thickness across the cell volume. The color intensity corresponds to the magnitude of thickness, where warmer hues indicate greater thickness (25–50 nm) and cooler hues denote thinner regions (0–25 nm). Left panel: virtual sections from representative control and *Msmeg\_fhaA* tomograms (control magnification 25,000 $\times$ ; *Msmeg\_fhaA* magnification 14,500 $\times$ ). White arrowheads indicate the plasma membrane. Notably, an increase in the middle layer (black arrows) is observed within the cell wall of *Msmeg\_fhaA*, contrasting with the consistently thinner layer exhibited in the control. Scale bar: 100 nm. Right panel: three-dimensional model of partial volumes of control and *Msmeg\_fhaA* cells. A predominant dark blue phenotype throughout the volume is observed for control strain, while there is a prevalence of warm hues along the majority of the *Msmeg\_fhaA* sampled volume, indicating the increase in the wall thicknesses. On the right side, cross-section view of different sequential slices along the Z axis. Numbers indicate where the models were sectioned.

between the two trajectories plus the spectral shift and broadening observed for the strain overexpressing FhaA can be attributed to changes in the molecular environment sensed by LAURDAN (Fig. 3B).

Altogether, our results indicate that FhaA overexpression has important impacts on mycobacterial cell envelope composition and/or structure.

### The overexpression of FhaA affects cell morphology

To investigate the effect of FhaA on elongation, we evaluated cell morphology of *Msmeg\_fhaA*. Confocal microscopy analysis of bacteria stained with sulforhodamine-1,2-dihexadecanoyl-sn-glycero-3-phosphoethanolamine (sulforhodamine-DHPE) revealed that the overexpression of FhaA led to significantly shorter cells, exhibiting an average length of  $4.5 \pm 0.1 \mu\text{m}$  (average length of control:  $7.0 \pm 0.2 \mu\text{m}$ ; Fig. 4A). This observation was subsequently corroborated through scanning electron microscopy (SEM), which revealed that *Msmeg\_fhaA* cells exhibit abnormal and heterogeneous morphology and dimensions, marked by shorter and wider cells with defects at poles and septum, the places where new cell wall material is incorporated. While in some cases swelling at the septum was observed, the vast majority of the cells presented defects at the poles (Fig. 2D and 4B). The aberrant morphology is distinguished by the thickening and curling of bacterial poles, with swollen and bulged tips that suggest compromised polar cell envelope integrity. Interestingly, these defects were mainly asymmetrical, being observed at one of the cell poles, with fewer cells presenting alterations at both poles (Fig. 4B). Ultrastructural analysis of cell poles by ET showed three cell wall layers as expected, with the middle layer displaying increased thickness in *Msmeg\_fhaA* when compared to the control strain (Fig. 2D; Video S1), suggesting an altered synthesis of the layers between the mycomembrane and inner membrane. The virtual section of a cell tomogram from an aberrant *Msmeg\_fhaA* pole corroborated the thickening of the cell wall (Fig. 2D and 4D). These observed morphological alterations thus suggest that FhaA overexpression disrupts normal polar cell elongation and cell wall synthesis.

### FhaA overexpression leads to the mislocalization of PG biosynthesis

Next, we evaluated the effect of FhaA overexpression on PG synthesis using the fluorescent D-amino acid analog 3-[[[(7-hydroxy-2-oxo-2H-1-benzopyran-3-yl)carbonyl]amino]-D-alanine hydrochloride (HADA) (38) to label the nascent PG. As expected, new cell wall material in the control strain is specifically inserted at the poles and septum (Fig. 5A). However, in the *Msmeg\_fhaA* strain, PG synthesis is not strictly confined to these sites, as HADA is additionally incorporated into discrete foci along the cell surface (Fig. 5A). To quantify the extent of PG synthesis delocalization, we assessed the distance between focal points of HADA incorporation in each bacterium, normalized to the cell length. As expected, we detected two or three local maxima of fluorescence intensity for the control strain (Fig. 5A and C) corresponding to the two poles (non-septate cells) or to the two poles plus the septum (septate cells), respectively (average number of HADA foci per cell:  $2.7 \pm 0.5$ ). In this case, the interspace between foci of PG synthesis correlates with the pole-septum or pole-pole distances as expected (Fig. 5B and C). For *Msmeg\_fhaA*, the average number of foci per cell increases to  $4.5 \pm 1.7$ , and the relative distance between foci is significantly shorter, indicating that the PG biosynthetic machinery is mislocalized (Fig. 5B and C).

The abnormal localization of the cell wall synthesis machinery, leading to bulges and branches, was previously shown for *M. smegmatis* strains overexpressing the elongasome scaffold Wag31 (39). To evaluate if the delocalization of the PG synthesis machinery could be associated with increased levels of Wag 31 in *Msmeg\_fhaA*, we performed a comparative analysis by mass spectrometry. The results confirmed the overexpression of FhaA, but Wag31 levels were not statistically different between *Msmeg\_fhaA* and control strain (Table S4). This result suggests that the elevated levels of FhaA could be the primary factor driving the delocalization of cell wall biosynthesis machinery.

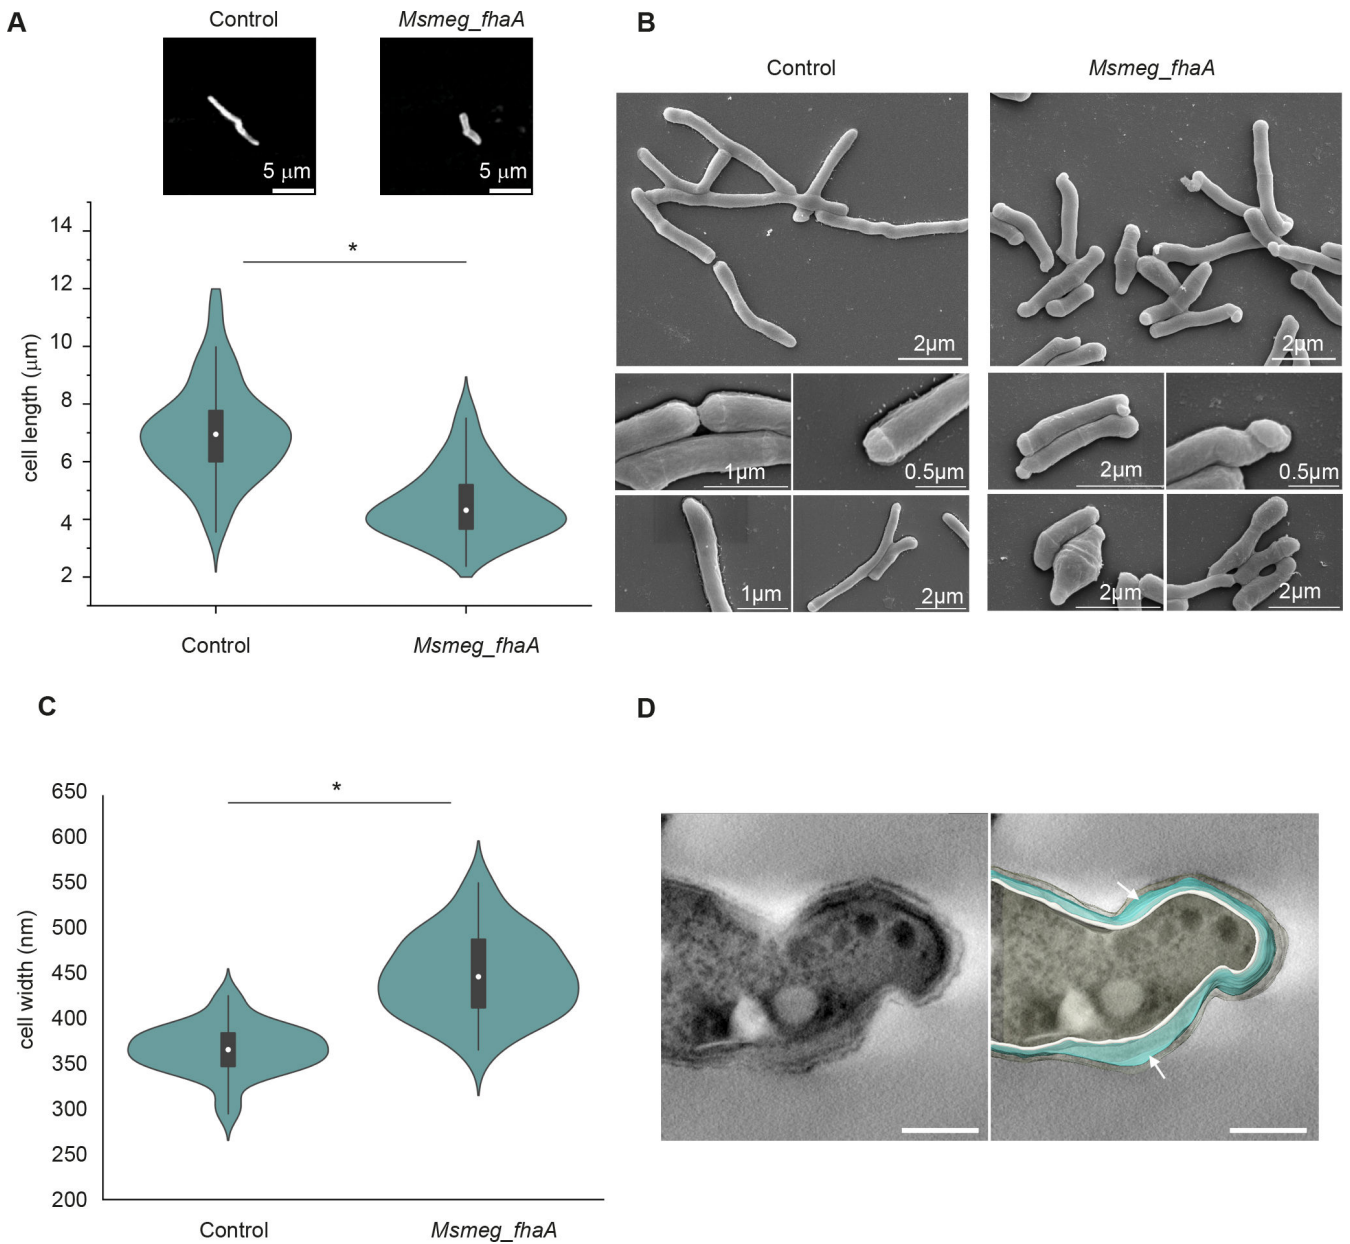

**FIG 3** Scanning confocal microscopy using the fluorescent dye LAURDAN. (A) Representative images for intensity and pseudocolor image of LAURDAN from of control and *Msmeg\_fhaA* strains. Pseudocolor images were generated by using the color scale indicated on panel B and represent spectral shift from blue to red. (B) Spectral phasor plot of LAURDAN fluorescence emission from control and *Msmeg\_fhaA* strains. Emission spectra were Fourier transformed into the G and S (corresponding to the real and imaginary parts of the first harmonic of the Fourier transform) to obtain the spectral phasor plot. Data indicate strong differences in envelope fluidity between strains, as measured by LAURDAN emission. The *Msmeg\_fhaA* strain clusters are shifted clockwise (blue-shifted) relative to the control strain and are further from the plot origin (indicating spectral widening). Additionally, the amplified section shows two different trajectories corresponding to each strain, clearly indicating different molecular environments for LAURDAN. (C) Plots illustrating normalized pixel intensity vs solid fraction. Black dots represent the control strain; white dots represent the *Msmeg\_fhaA* strain. (D) Box plot representing the values of the center of mass for the curves depicted in panel C.

### FhaA is necessary for asymmetric polar elongation

To further investigate the role of FhaA in elongation, we evaluated the cell morphology and HADA incorporation for a strain lacking FhaA (*Msmeg\_ΔfhaA*). In accordance with a previous report (15), *Msmeg\_ΔfhaA* cells were shorter than the wild-type (WT) strain, and cell length was partially recovered after complementation (Fig. 6A) confirming a role for FhaA in cell elongation.

Fluorescence intensity profiles in dividing WT cells revealed the presence of three maxima at septum and poles (Fig. 6B), with the poles exhibiting a greater intensity and

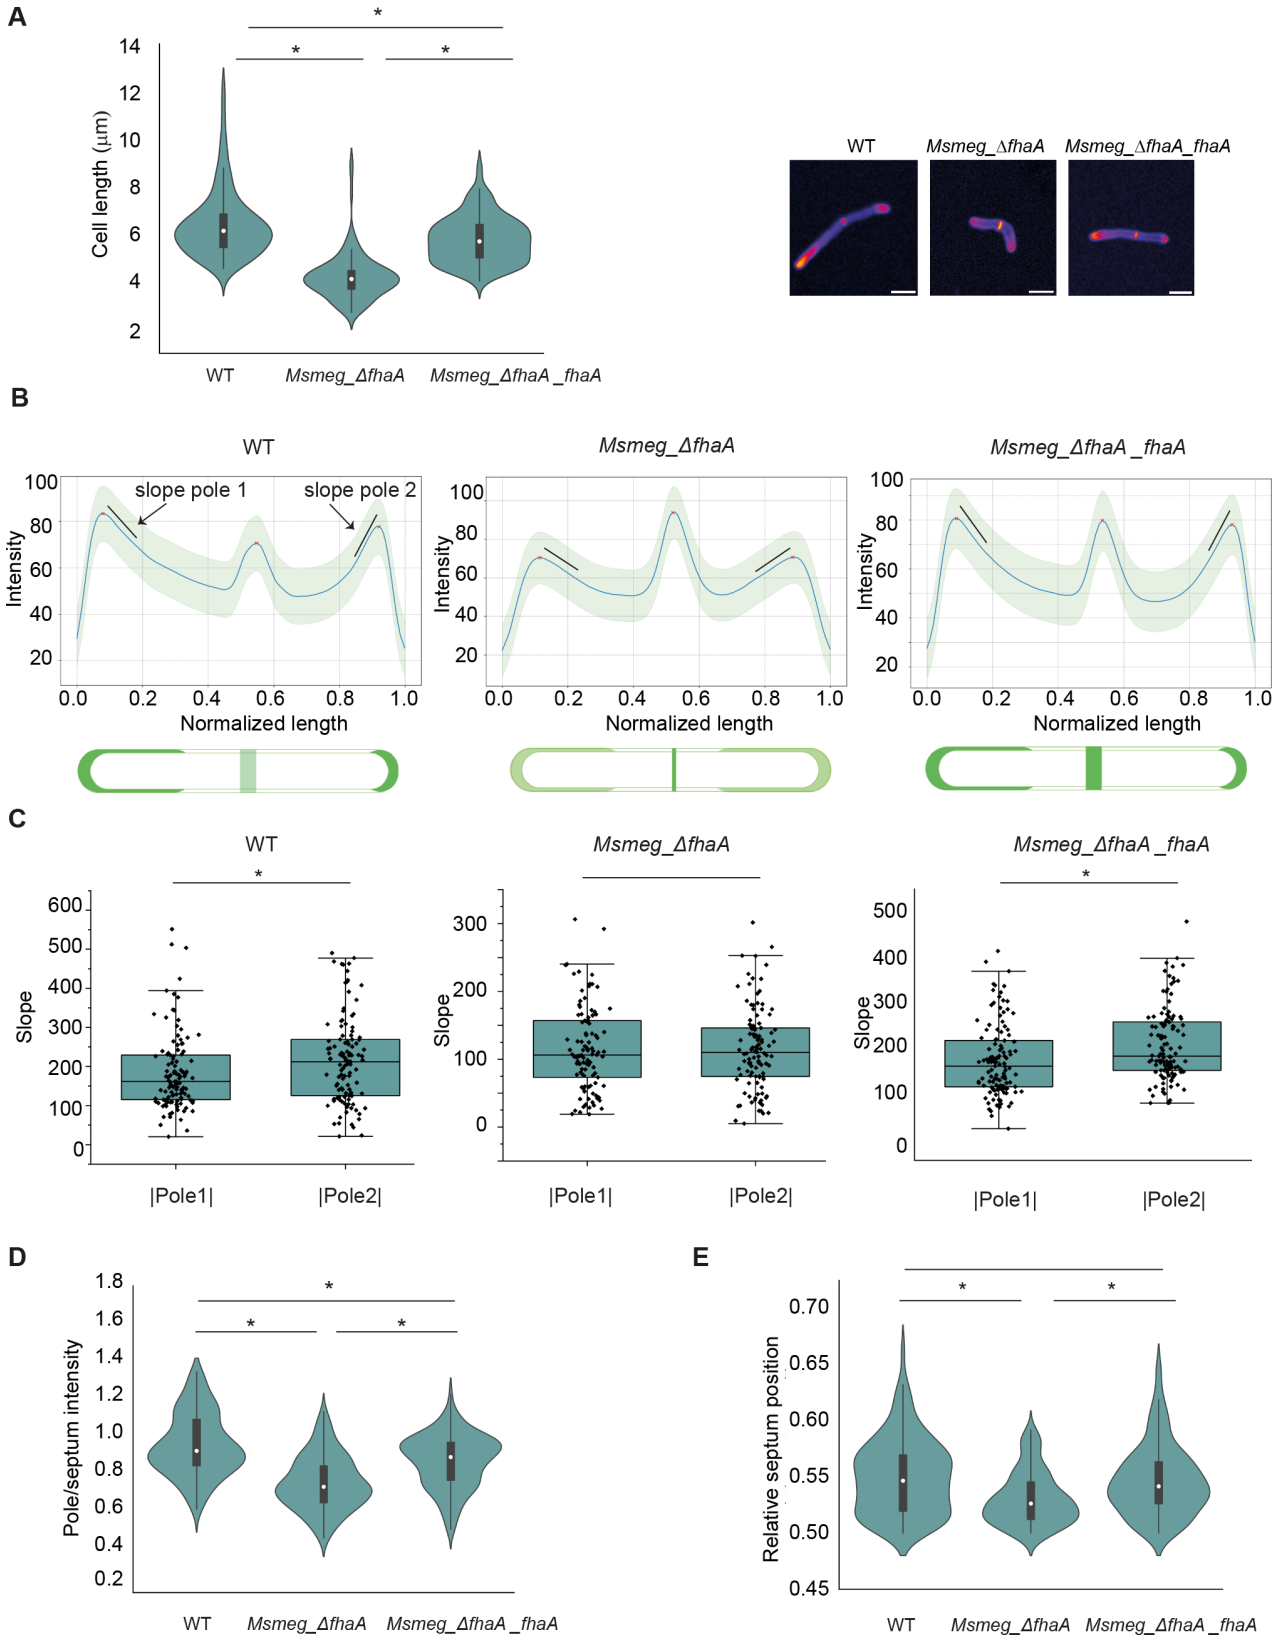

**FIG 4** FhaA overexpression alters cell morphology. (A) Violin plot and representative images of sulforhodamine-DHPE stained bacteria illustrating differences in cell length between both strains. Average length is  $7.0 \pm 0.2 \mu\text{m}$  for control strain and  $4.5 \pm 0.1 \mu\text{m}$  for *Msmeg\_fhaA* strain. \* indicates statistically significant difference determined by two samples t-test.  $P < 0.05$ ;  $n > 100$  cells for each group. White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers. (B) SEM showing morphological differences between strains. Images of *Msmeg\_fhaA* strain reveal a heterogeneity in cell shapes, length, and width when compared to control. In addition, most of the *Msmeg\_fhaA* cells exhibit one aberrant pole. (C) Violin plot showing that cell width is altered in *Msmeg\_fhaA* strain. Measurements of cell width were performed from SEM images. \* indicates statistically significant difference determined by one-way ANOVA.  $P < 0.05$ ;  $n = 30$  cells for each group. White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers. (D) Left: virtual section of *Msmeg\_fhaA* cell tomogram with a “curved” tip. Right: top view of the 3D model, emphasizing the thickening of the cell wall (white arrows), which alters the cell topography near the tip, contributing to the observed curved phenotype. White layer represents the plasma membrane; light blue indicates PG/arabinogalactan; light yellow indicates outer membrane. Scale bar: 200 nm.

asymmetric elongation, as reported previously (6, 40, 41). The faster-growing pole showed HADA signals covering a broader area from the tip, and a smaller slope of fluorescence intensity (Fig. 6A and B). Conversely, the fluorescence signal at the slower-growing pole appears concentrated within a more restricted region, and the slope in the

**FIG 5** FhaA overexpression leads to mislocalization of the PG synthesis machinery. (A) Representative images of control and *Msmeg\_fhaA* strains showing PG synthesis distribution. Fire Look up tables (LUT) was applied to HADA signal to enhance the visibility of regions with higher fluorescence intensity. *Find maxima* tool of Image J was used to detect local intensity maxima for the HADA signal (white crosses), and distances between focuses were measured (cyan sticks). As the cell length is significantly different among both strains, distances between foci were relativized to cell length (yellow sticks). Scale bars: 5  $\mu$ m. (B) Violin plot showing the differences in the distribution of distances between foci for control and *Msmeg\_fhaA* strain. Distance between foci (poles and septa) for septate control strain oscillates between 50/50 and 70/30 of the total cell length, as expected. \* indicates statistically significant difference determined by Kolmogorov-Smirnov,  $P < 0.05$ ;  $n > 100$  cells for each group. White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers. (C) Violin plot showing that number of HADA foci per cell is increased in *Msmeg\_fhaA* strain. Control cells exhibit two foci (both poles, non-septate bacteria) or three (two poles and septum, septate bacteria). *Msmeg\_fhaA* cells exhibit multiple foci, even when non septate. \* indicates statistically significant difference determined by Kolmogorov-Smirnov,  $P < 0.05$ ;  $n > 100$  cells for each group. White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers.

**FIG 6** FhaA is necessary for asymmetric polar elongation. outliers. Scale bar 2  $\mu\text{m}$ . (B) Average HADA fluorescence profiles along the cell for >100 septate cells. Blurred zone represents SD. Profiles consist in three peaks corresponding to both poles (named pole 1 and pole 2) and septum. For WT, maximum intensity is located at poles, while for *Msmeg\_ΔfhaA* strain, the maximum intensity is located at septum. *Msmeg\_ΔfhaA\_fhaA* exhibits an intermediate phenotype exhibiting three peaks of comparable intensity. The schemes below represent HADA deposition patterns for each strain. (C) Box plots showing the slope (black lines in fluorescence profiles) at pole 1 and pole 2 for >100 cells allowed to corroborate the asymmetric growth for WT and *Msmeg\_ΔfhaA\_fhaA*. For *Msmeg\_ΔfhaA*, HADA incorporation at both poles was undistinguishable. \* indicates statistically significant difference determined by Kolmogorov-Smirnov test,  $P < 0.05$ ;  $n > 100$  cells for each group. Box represents 25%–75% percentile and median; values outside whiskers represent outliers. (D) Violin plot illustrating the ratio between intensity at poles (average of both) and intensity at septum. \* indicates statistically significant difference determined by one-way ANOVA.  $P < 0.05$ ;  $n > 100$  cells for each group. White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers. (E) Violin plot showing the distribution of the relative septum position in WT, *Msmeg\_ΔfhaA*, and *Msmeg\_ΔfhaA\_fhaA* strains. The asymmetrical position of the septum is lost in *Msmeg\_ΔfhaA* strain, and it is completely restored after complementation. \* indicates statistically significant difference determined by one-way ANOVA.  $P < 0.05$ ;  $n > 100$  cells for each group. White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers.

fluorescence intensity profile is higher (Fig. 6A through C), confirming a statistically significant difference in the extent of HADA incorporation for the WT strain (Fig. 6A and C). However, *Msmeg\_ΔfhaA* displays a distinct HADA profile characterized by an increased intensity at the septum and significantly lower levels of HADA incorporation at the poles (Fig. 6B). The ratio of pole intensity/septum intensity (with pole intensity as the average of both poles) is significantly different between WT and *Msmeg\_ΔfhaA*, and this abnormal distribution of PG synthesis is partially reverted after complementation (Fig. 6D; Fig. S3A). In addition, the polar incorporation of HADA by *Msmeg\_ΔfhaA* encompasses a broader area at both poles, when compared with WT. Surprisingly, the deletion of FhaA not only altered the pattern and quantity of HADA incorporation but also resulted in a symmetrical polar incorporation of new cell wall material, as revealed by the average fluorescence profile and the similar slope of fluorescence intensity at each pole in *Msmeg\_ΔfhaA* (Fig. 6B and C). Moreover, this slope is smaller than that measured for the fast-growing pole of WT which, together with the observation that *Msmeg\_ΔfhaA* cells are shorter, indicates a more diffuse localization of the PG synthesis machinery (Fig. 6B and C; Fig. S3B). It is important to note that the complementation of *Msmeg\_ΔfhaA* completely recovers polar cell wall synthesis and asymmetric PG incorporation (Fig. 6B and C; Fig. S3A and B).

As a consequence of the well-documented differences in growth rates between the old and new poles, mycobacteria exhibit an asymmetric position of the septum and considerable variability in cell size among the population. Thus, we assessed septum position and cell length variability in *Msmeg\_ΔfhaA*. Consistent with the loss of asymmetric growth, in the *fhaA* deletion strain, the septum is positioned closer to the midcell compared to WT, while the septal position asymmetry is restored after complementation (Fig. 6E). The loss of asymmetric growth in *Msmeg\_ΔfhaA* is further confirmed by a more homogeneous population in length, compared to either the WT or the complemented strain (Fig. 6A). Moreover, using an *M. smegmatis* strain overexpressing FhaA fused to the fluorescent protein mScarlet (*Msmeg\_mscarlet\_fhaA*), we showed that the protein localizes to the poles and septa as anticipated, with a predominant localization at one of the poles. To determine if FhaA preferentially localizes to the old or new pole, we conducted experiments before HADA delocalization occurred but when mScarlet-FhaA the expression was already evident. In this manner, we confidently identified the fast and slow PG incorporating poles. This approach allowed us to demonstrate that FhaA preferentially accumulates at the old, fast-growing pole (Fig. 7).

## DISCUSSION

The cellular growth of mycobacteria is distinguished by the incorporation of new cell wall material at the poles in an asymmetric manner, with the old pole inherited from the mother cell growing faster than the new pole formed after the last division. This asymmetry leads to a heterogeneous population in terms of size, growth

**FIG 7** FhaA localizes preferentially at the old pole. (A) Box plot showing differences in the distribution of mScarlet-FhaA fluorescence intensity at both poles. Poles were classified as old and new based on the pattern of HADA fluorescence incorporation. The top asterisk indicates a statistically significant difference determined by two samples *t*-test  $< 0.05$ ;  $n = 30$  cells. White circles represent median; gray boxes represent 25%–75% percentile; values outside whiskers represent outliers. (B) Representative images of an *Msmeg\_mscarlet\_fhaA* cell showing colocalization of HADA signal and mScarlet-FhaA at poles and septum. mScarlet-FhaA accumulates preferentially at the old pole. Scale bar: 5  $\mu$ m.

rate, and antibiotic susceptibility, which is critical for *M. tuberculosis* pathogenesis and the development of antibiotic-resistant strains. Despite its importance, the molecular mechanisms that sustain asymmetric polar growth are still not well understood. Here, we present strong evidence that FhaA is a key elongation factor predominantly localizing to the old pole and crucial for cell envelope integrity and the asymmetry of polar growth.

The FhaA architecture of two modular domains separated by a flexible linker is highly reminiscent of eukaryotic scaffolding proteins (10, 13). This protein organization suggests that FhaA could have a tethering role, bringing together different molecular machineries. Our interactomic analysis shows that FhaA is part of a protein network involved in the biosynthesis of different layers of the complex mycobacterial cell envelope, including proteins associated with PG, LM/LAM, and mycolic acid synthesis and transport. These findings are in line with, and extend, the previous observation that FhaA interacts with the Lipid II flippase Mvin (10). Consistently, the FhaA interactome significantly overlaps with those reported for other well-known components of the *Mycobacteriales* elongasome/divisome, namely MmpL3 and FtsQ (18, 26, 42) (Table S1 and S2), and several of the proteins identified in our work (FhaA itself, MSMEG\_0317, MSMEG\_5048, atpC, MmpL3, NusA, and WhiA) were shown to interact with mycolates *in vivo* using photoactivatable TMM analogs (43) (Table S1 and S2).

In line with these results, overexpression of FhaA led to alterations in the cell envelope composition and structure. The decreased surface hydrophobicity, along with the impairment in biofilm formation of the *Msmeg\_fhaA* strain, points to defective biosynthesis or stability of the mycomembrane and/or the underlying layers of the cell wall. The release of significant amounts of membrane fragments containing mycolic acid esters of trehalose, resulting from impaired mycomembrane stability, has been reported for a *Corynebacterium glutamicum* strain defective in arabinogalactan synthesis (44). Our ET analysis reveals irregular thickening of the cell wall layer between the two membranes in the strain overexpressing FhaA, providing a potential explanation for the observed phenotypes. Finally, our analysis of LAURDAN fluorescence indicates an altered fluidity of the cell envelope lipidic layers. Nevertheless, considering our data as a whole, we are inclined to speculate that the perturbation of the intermediate layers of the cell envelope could be responsible for the change in polarity and water relaxation sensed by LAURDAN. Altogether, our interactome and phenotypic characterization strongly

indicate that FhaA is a part of the molecular machinery responsible for the synthesis of the complex cell envelope of mycobacteria and plays a functional role in this biosynthetic process.

We confirmed that FhaA localizes preferentially to the poles and septum, as previously reported (10). Furthermore, our quantitative analyses revealed an asymmetric distribution between the poles, with a higher concentration of FhaA specifically at the old pole. During growth and division, PG synthesis is orchestrated by two multiprotein complexes: the elongasome responsible for polar elongation and the divisome responsible for cell division and septation. The short cell phenotype of *Msmeg\_ΔfhaA* cells, together with a lower HADA incorporation at the poles, clearly indicates that FhaA partakes in polar PG synthesis and normal cell elongation. A previous report showed that FhaA depletion results in an increased accumulation of nascent PG stem peptides at the cell poles and septum and thus propose that FhaA inhibits the late stages of PG biosynthesis via its interaction with Mvin (10). Our results consistently support the role of FhaA in this process, but based on HADA incorporation and morphological characterizations, we hypothesize that FhaA promotes PG synthesis. In addition, the characteristic asymmetric growth pattern of mycobacteria is lost in the absence of FhaA. Collectively, our results establish FhaA as a bona fide functional partner of the elongasome, essential for asymmetric polar elongation. Further supporting this hypothesis, the recruitment to the old pole of the FhaA's top interactor PgfA, which shares the same localization pattern as FhaA, is known to be essential for establishing cellular asymmetry (17). The uneven distribution of key components of the cell elongation machinery, predominantly concentrated at the old pole, has been previously demonstrated and provides a plausible explanation for the differential polar growth rates (5, 45–48). A biphasic growth model has been proposed, in which the new pole undergoes an initial phase of slower growth, during which Wag31 accumulates, followed by a period of rapid growth prior to the next division cycle (41). Another report suggests that the molecular basis for the polar growth of fast and slow poles is fundamentally different (17).

Various pieces of evidence in this work indicate that FhaA affects the precise subcellular localization of new cell wall material insertion. First, overexpression of FhaA leads to the insertion of HADA at multiple focal points along the cell length, as well as at the poles and septa, a phenotype that is not due to increased levels of Wag31 but seems to be directly linked to altered levels of FhaA. In parallel, TEM and ET reveal a heterogeneous cell wall with localized thickening, strongly suggesting that these enlarged areas of the cell wall can be correlated with the extra foci of HADA incorporation and the mislocalization of the elongasome machinery. Consistently, in the strain lacking FhaA, HADA incorporation extends over a broader region at the poles, surpassing even the area observed in the fast-growing pole of the WT strain. As *Msmeg\_ΔfhaA* cells are shorter, the extended area of HADA incorporation suggests that the biosynthetic machinery is less positionally constrained at the poles, rather than indicating rapid growth. Taken together, our results indicate that FhaA participates in the regulation of the accurate localization of the elongasome and its biosynthetic activity.

Asymmetric growth is a key trait for mycobacteria adaptation and successful survival strategies, promoting heterogeneous populations with varied responses to environmental challenges and drugs. Thus, uncovering central molecular actors in this essential process deepens our understanding of mycobacterial biology while also identifying promising drug target candidates.

## MATERIALS AND METHODS

### Bacterial strains and growth conditions

The *M. smegmatis* strains overexpressing Strep-tagged FhaA (hereinafter referred to as *Msmeg\_fhaA*), mScarlet-FhaA (referred to as *Msmeg\_mscarlet\_fhaA*), and the control strain were obtained as previously described (49). Briefly, electrocompetent *M. smegmatis*

mc<sup>2</sup> 155 was transformed with a pLAM12 plasmid containing the coding region of the gene Rv0020c (*fhaA* of *M. tuberculosis*) plus an N-terminal tag (Strep-tag II), or the gene Rv0020c plus the sequence of the red fluorescent protein mScarlet (50) at the N-terminus, both under the control of the *M. smegmatis* acetamidase promoter. As a control, *M. smegmatis* mc<sup>2</sup> 155 transformed with an empty version of the pLAM12 plasmid was used (control). *M. smegmatis* strains were maintained on Middlebrook 7H10 agar plates (Difco) plus 10% albumine/dextrose/catalase (ADC) (0.2% dextrose, 0.5% bovine serum albumin, and 0.085% NaCl). Liquid cultures were grown in Middlebrook 7H9 (Difco) plus 10% ADC and 0.05% (vol/vol) Tween 80 at 37°C and 220 r.p.m. until reaching an OD<sub>600</sub> = 0.8. All media were supplemented with kanamycin (50 µg/mL) and ampicillin (100 µg/mL). Expression of Strep-tag II-FhaA was induced by the addition of 0.2% acetamide during the exponential growth phase (OD<sub>600</sub> = 0.2). For interactomic analyses, five independent cultures of each strain were prepared.

The *M. smegmatis* mc<sup>2</sup> 6 strain knockout for *fhaA* (*Msmeg\_ΔfhaA* in this work), along with the corresponding control strain (*M. smegmatis* mc<sup>2</sup> 6, WT in this work) and the *fhaA* knockout complemented with MSMEG\_0035 (*Msmeg\_ΔfhaA\_fhaA*), was kindly provided by Dr. Raghunand Tirumalai (15). A table with all the strains of *M. smegmatis* mc<sup>2</sup> 6 and its derived strain *M. smegmatis* mc<sup>2</sup> 155 used in this work is presented in Table S5.

### Chemical crosslinking in living cells

Chemical crosslinking was performed following the protocol previously used (51, 52). Briefly, after 18 h of induction, cultures were incubated with formaldehyde (final concentration 0.5%) at 37°C and 220 r.p.m. for 20 min, and the excess of formaldehyde was quenched by the addition of 1/10 culture volume of ice-cold glycine (125 mM) in phosphate-buffered saline (PBS) for 20 min.

### Affinity purification of protein complexes

Cell cultures were harvested by centrifugation, washed with PBS and re-suspended in 25 mM HEPES, 150 mM NaCl, 1% glycerol, 1 mM EDTA, pH 7.4, 1× protease inhibitor cocktail (Roche), 1× phosphatase inhibitor (Sigma-Aldrich), and 1.0% Triton X-100 (vol/vol). Lysates were obtained by sonication on ice (25% amplitude, 10 s on, 30 s off; total cycle: 8 min) followed by three cycles of 10 min vortexing in the presence of glass beads (Glass beads, acid-washed ≤ 106 µm, Sigma-Aldrich) with 20 min intervals. After centrifugation, protein concentration of the supernatants was determined by densitometric analysis on SDS-PAGE gels.

FhaA protein complexes were purified using a commercial affinity resin (Strep-Tactin Sepharose, IBA Solutions). Supplier's protocol was optimized, including extra washing steps with 1% Triton X-100 to decrease the number of unspecific interactions recovered. Elution was performed using D-desthiobiotin. As mock, protein extracts from control strain were submitted to the same purification protocol.

### Sample preparation for MS analysis

For interactome analysis, purified complexes (five replicates for each strain) were digested in solution at 37°C overnight after Cys reduction (10 mM Dithiothreitol (DTT) and alkylation (55 mM iodoacetamide). Peptide mixtures were desalted using micro-columns (C18 ZipTip, Merck, Millipore), eluted in 0.1% formic acid in ACN, and dried and resuspended in 0.1% formic acid prior to its analysis by nano-LC MS/MS.

### Nano-liquid chromatography-tandem mass spectrometry analysis

Analysis of peptide mixtures was performed using liquid chromatography-tandem mass spectrometry. Peptides were separated using a nano-HPLC system (EASY-nLC 1,000, Thermo Scientific) equipped with a reverse-phase column (EASY-Spray column, 15 cm × 75 µm ID, PepMap RSLC C18, 2 µm, Thermo Scientific) and a precolumn (Acclaim Pepmap

100 C18 3  $\mu\text{m}$ , 75  $\mu\text{m} \times 20$  mm, Thermo). Elution was performed at a constant flow rate of 250 nL/min with a two-solvent system (A: 0.1% formic acid in water and B: 0.1% formic acid in acetonitrile) and the following gradient: 0%–50% B over 100 min and 50%–100% B over 10 min. Column temperature was set to 45°C. For total proteome analysis, three replicates of each strain were used. Sixty-eight milligram of total protein extracts was loaded on SDS-PAGE (12%). The gel was fixed and stained, and each lane was excised into four gel pieces that were processed for MS analysis as previously described (53). Briefly, Cys reduction and alkylation were performed by incubation with 10 mM DTT at 56°C followed by 45 min incubation with 55 mM iodoacetamide at room temperature. In-gel tryptic digestion (Sequencing Grade Modified trypsin, Promega) was performed overnight at 37°C, and peptide extraction was carried out by consecutive incubations with 0.1% trifluoroacetic acid in 60% acetonitrile. Extracted peptides were vacuum dried and resuspended in 0.1% formic acid.

Nano-HPLC was coupled to a linear ion trap mass spectrometer (LTQ Velos, Thermo Scientific). Nano electrospray ionization source parameters were set as follows: spray voltage 2.3 kV and capillary temperature 260°C. The equipment was operated in a data-dependent acquisition mode: a full MS scan acquired in positive ion mode ( $m/z$  between 300 and 1,800 Da) was followed by fragmentation of the 10 most intense ions (normalized collision energy: 35; activation Q: 0.25; activation time: 15 ms) using a dynamic exclusion list.

### Bioinformatics analyses

Bioinformatics data analysis was performed using PatternLab for Proteomics V5 (<http://patternlabforproteomics.org>) (54). A target-decoy database was generated using *M. smegmatis* strain ATCC 700084/MC2155 sequences (downloaded from Uniprot on 29 March 2016) plus the sequence of the Strep-tagged FhaA and 127 most common mass spectrometry contaminants. Search parameters were set as follows: tryptic peptides; oxidation of Met as variable modification; carbamidomethylation as fixed Cys modification; 800 ppm of tolerance from the measured precursor  $m/z$ . Search Engine Processor was used to filter peptide spectrum matches to a false discovery rate (FDR) < 1% at the protein level. Identification of proteins exclusively detected in FhaA-purified-crosslinked complexes was performed using PatternLab's Approximately Area Proportional Venn Diagram module. Proteins present in at least four out of five *Msmeg\_fhaA* replicates, but absent in all control replicates, and statistically validated using the Bayesian model integrated into PatternLab for proteomics Venn Diagram module were considered part of FhaA interactome. In addition, TFold module was used to pinpoint proteins statistically enriched in FhaA complexes according to their spectral counts (BH  $q$  value: 0.05, F Stringency: 0.04, and L-stringency: 0.6) (55, 56).

### Cell surface hydrophobicity test

Surface hydrophobicity was quantified using the Microbial Adhesion to Hydrocarbon method (57). For that purpose, cells were partitioned using a two-phase system, according to previous reports (58). Exponential growth phase cultures were washed and resuspended in PBS until a final OD600 of 0.7. Samples were mixed with xylene in a 1:1 ratio and incubated 15 min at room temperature to allow partitioning. OD600 of aqueous layer was determined. Hydrophobicity index represents the percentage of initial aqueous layer absorbance retained in the xylene fraction after partitioning. Experiments were performed in triplicate.

### Biofilm formation assay

Microtiter dish biofilm formation assay was performed as previously described (53). Briefly, bacterial cultures were loaded in 96-well plates to an initial OD600 of 0.1. Biofilm formation was evaluated by biological triplicates when static cultures of both strains reached identical OD600. Staining was performed with crystal violet. Biofilms were

destained in 30% acetic acid, and OD570 of the retained crystal violet was determined. Experiments were performed in triplicate.

### Ethidium bromide permeability test

Permeability test was performed according to (15). Briefly, exponential growth phase cultures were washed with 50 mM  $\text{KH}_2\text{PO}_4$  pH 7.5 mM  $\text{MgSO}_4$  and resuspended at an OD600 of 0.5, pre-energized for 5 min with 0.4% glucose and loaded into 96-well fluorescence plates. Ethidium bromide was added at a final concentration of 20  $\mu\text{M}$ , and measurements were performed at 37°C in a Varioskan plate reader ( $\lambda_{\text{ex}} = 530$  nm and  $\lambda_{\text{em}} = 590$  nm). Kolmogorov Smirnov test was used.

### Growth curve

To ensure that observed differences in biofilm formation are not due to differences in biomass, a static growth curve was recorded, with cells grown in the same conditions used for biofilm assays. Briefly, 96-well plates were loaded with three independent cultures of each strain in quintuplicate and incubated at room temperature without shaking. OD600 was measured once a day for 10 days.

### Fluorescence microscopy and image acquisition and analysis

Exponential growth phase cultures were incubated with 50  $\mu\text{M}$  HADA for 30 min. Samples were loaded into glass slides and allowed to dry at 37°C. Sulforhodamine-DHPE 10  $\mu\text{g}/\text{mL}$  was added and allowed to dry. Slides were washed with sterile water and mounted in 10% bovine serum albumin. Images were acquired with a Zeiss LSM 880 confocal laser scanning microscope, equipped with a plan-apochromatic 63 $\times$ /1.4 oil immersion objective. Image acquisition was performed in channel mode with a pixel size of 0.105  $\mu\text{m}$  and a resolution of 256  $\times$  256. HADA excitation was performed with a 405 nm laser, and emitted light was collected in the range between 415 and 480 nm. Sulforhodamine-DHPE excitation was performed using a 561 nm laser, and light emission was collected between 580 and 620 nm. mScarlet excitation was performed using a 561 nm laser, and emitted light was collected in the range between 570 and 655 nm.

Images were processed and analyzed using Image J (59). All cell length measurements were performed using the Sulforhodamine-DHPE signal; all calculated parameters were obtained from the HADA or mScarlet-FhaA signals.

Control HADA foci were detected using *Find maxima tool* of Image J. Prominence was set to detect 2 (non-septate) or 3 (septate) foci per cell in control strain. The same setting was then applied to *Msmeg\_fhaA* strain. For comparative purposes, and to account for differences in cell length, distances between HADA foci were expressed as a fraction of the total length.

For WT, *Msmeg\_ΔfhaA*, and *Msmeg\_ΔfhaA\_fhaA* analysis, we use ImageJ to obtain the intensity profile of HADA drawing a segmented line across the longitudinal axis. The line has a width of 10 pixels, corresponding to approximately 1.06  $\mu\text{m}$ , and a spatial resolution of 0.09  $\mu\text{m}$ . Each profile is computed as the average intensity across the line width, and cell length was normalized. For each strain, we compute a representative profile by averaging all the bacteria profiles in the strain. Also, we obtained the position and intensity of the septum and poles for each bacterium in the strain by using *findpeaks* Scipy function. The septum position was ultimately utilized to select and align both the old and new poles, with the new pole positioned closest to the septum. To determine the pole intensity decay toward the septum, we consider 10 points of the profile curve and fit it to a first-order polynomial. We consider the slope of the fit curve as the value representing the decay.

For the *Msmeg\_mscarlet\_fhaA* analysis, ImageJ was used to extract the HADA fluorescence profile, following the procedure described above. Profiles of each individual bacterium were length-normalized and aligned according to their type of pole (old or

new). This classification allowed us to determine the fluorescence intensity of mScarlet-FhaA associated with each type of pole.

Statistical comparisons between strains were performed using one-way ANOVA or *t*-test for normally distributed data and Kolmogorov-Smirnov (two samples) or Kruskal-Wallis (three samples) for not normally distributed data.

### Sample preparation for transmission electron microscopy

For TEM analysis, samples were fixed with 2.5% glutaraldehyde and 4% formaldehyde in 0.1 M cacodylate buffer (pH 7.2) for 2 h and post-fixed for 1 h in 1% OsO<sub>4</sub> with 2.5% potassium ferrocyanide in the same buffer. Samples were then dehydrated in acetone and embedded in Polybed 812 resin (Polysciences). Ultrathin (60 nm) sections were stained with 5% uranyl acetate (40 min) and 2% lead citrate (5 min) before observation using a JEOL 1200 EX transmission electron microscope at 120 kV equipped with a camera Megaview G2 CCD 1 k.

### Electron tomography

As previously established for electron tomography (60–62), samples processed for TEM were sectioned (200 nm thick serial sections) in a PowerTome XL ultramicrotome (RMC Boeckeler) and collected onto formvar-coated copper slot grids, then stained with 5% (wt/vol) uranyl acetate and lead citrate. In addition, 10 nm colloidal gold particles (Gold colloid, Sigma-Aldrich) were used as fiducial markers during the tilted series' alignment. Finally, a single-axis tilt series ( $\pm 65^\circ$  with  $2^\circ$  increment) was collected from the samples using a Tecnai G2 F20 transmission electron microscope (Thermo Fisher Scientific) operating at 200 kV in TEM mode with a camera AMT CMOS 4K. Tomographic tilt series were processed using IMOD version 4.9.13 (University of Colorado, USA). Projections were aligned by cross-correlation. The final alignment was performed using 10 nm fiducial gold particles followed by weighted back-projection reconstruction. Manual segmentation, surface rendering, and thickness map analysis were performed with the Amira software (Thermo Fisher Scientific).

### Scanning electron microscopy

Samples were fixed with 2.5% glutaraldehyde and 4% formaldehyde in 0.1 M cacodylate buffer (pH 7.2) for 2 h and then adhered to poly-L-lysine treated coverslips. Next, the coverslips were washed with 0.1 M sodium cacodylate buffer and post-fixed for 40 min in 1% OsO<sub>4</sub> with 2.5% potassium ferrocyanide. After another washing cycle of three rounds, the samples were dehydrated through a series of increasing concentrations (30%–100%) of ethanol. Finally, the samples were critical-point-dried in liquid CO<sub>2</sub> in a Leica EM CPD300 apparatus and sputtering with a 2-nm-thick platinum coat in a Quorum Q150V Plus apparatus. Samples were observed using a field emission gun Quattro S scanning electron microscope (Thermo Fisher Scientific) operating at 5 kV.

### Morphometry

Cell wall thickness measurements were carried out on images obtained from ultra-thin TEM sections, whereas cell width measurements were derived from SEM images using the Fiji/Image J software. Two opposing regions of each cell were assessed for thickness, while three regions (ends and center) of each cell were measured for width. The mean values were calculated based on data obtained from 30 cells in each experimental group. Statistical analyses were conducted using the Kolmogorov Smirnov (TEM) or one-way ANOVA (SEM), with significance set at  $P < 0.05$ .

### LAURDAN staining, image acquisition, and spectral phasor analysis

Exponential growth phase cultures (OD<sub>600</sub> 0.8) were centrifuged and washed in PBS. Pellets were resuspended in 50  $\mu$ L of 0.05 mM LAURDAN-dimethyl sulfoxide in PBS

and incubated at 37°C and 220 rpm for 2 h. Live bacteria were mounted in agarose patches and visualized using a Zeiss LSM 880 spectral confocal laser scanning microscope, equipped with a plan-apochromatic 63×/1.4 oil immersion objective. LAURDAN excitation was performed in lambda mode, using a 405 nm laser for excitation, and emission was collected in the range from 418 to 718 nm, in 30 channels, 10 nm each, and an extra channel for transmitted light. Images were acquired with a 256 × 256 pixel resolution and a scan zoom of 10× (pixel size 0.05 × 0.05 μm; pixel time 0.67 μs). As LAURDAN emission spectrum is sensitive to the lipid composition and dipolar relaxation, it may be used to assess water accessibility in the environment in which the probe is embedded. Spectral phasor analysis of LAURDAN emission was performed using the fluorescence lifetime imaging module of SimFCS 4 software ([www.lfd.uci.edu/globals](http://www.lfd.uci.edu/globals)). Briefly, LAURDAN emission spectra from each pixel were Fourier transformed, and G and S (corresponding to the real and imaginary parts of the first harmonic of Fourier transform) were used as x and y coordinates of the phasor plot. Pixels with similar spectral properties cluster together on the plot. While the angular position (Φ) of clustered pixels into the phasor plot provides information about the emission-spectra-center-of-mass, spectral widening relies on radial position (M). Each pixel of the image is associated with a phasor in the phasor plot, and each phasor maps to pixels in the image.

## ACKNOWLEDGMENTS

We express our gratitude to Magdalena Portela for the excellent technical support and to Dr. Adriana Parodi for her insightful discussions on the results. We also thank Dr. Raghunand Tirumalai for kindly providing us with the  $mc^2$  6 strains (*Msmeg\_ΔfhaA*, *Msmeg\_ΔfhaA\_fhaA*, and WT). We extend our gratitude to Dr. Martin Graña for his critical review and valuable contributions to improving the manuscript and BSc. Bruno Schuty for fruitful discussions.

## AUTHOR CONTRIBUTIONS

Jessica Rossello, Conceptualization, Formal analysis, Investigation, Validation, Visualization, Writing – original draft, Writing – review and editing | Bernardina Rivera, Investigation, Writing – review and editing | Maximiliano Anzibar Fialho, Data curation, Formal analysis, Writing – review and editing | Ingrid Augusto, Formal analysis, Investigation, Visualization, Writing – review and editing | Magdalena Gil, Formal analysis, Investigation, Writing – review and editing | Marina Andrea Forrellad, Investigation, Writing – review and editing | Fabiana Bigi, Investigation, Supervision, Writing – review and editing | Azalia Rodríguez Taño, Investigation, Visualization, Writing – review and editing | Estefanía Urdániz, Investigation, Writing – review and editing | Mariana Piuri, Investigation, Supervision, Writing – review and editing | Kildare Miranda, Supervision, Writing – review and editing | Anne Marie Wehenkel, Conceptualization, Investigation, Supervision, Writing – review and editing | Pedro M. Alzari, Conceptualization, Funding acquisition, Supervision, Writing – review and editing | Leonel Malacrida, Formal analysis, Supervision, Writing – review and editing | Rosario Durán, Conceptualization, Formal analysis, Funding acquisition, Investigation, Project administration, Supervision, Validation, Writing – original draft, Writing – review and editing

## DATA AVAILABILITY

The mass spectrometry interactomics data have been deposited to the ProteomeX-change Consortium via the PRIDE partner repository with the data set identifier [PXD054354](https://doi.org/10.1093/ptm/000000000000063) (63).

## ADDITIONAL FILES

The following material is available [online](#).

### Supplemental Material

**Figure S1 (mBio02526-24-s0001.tif).** Static growth curve and permeability assay of *Msmeg\_fhaA* and control strains.

**Figure S2 (mBio02526-24-s0002.tif).** TEM images showing differences on cell wall thickness between control and *Msmeg\_fhaA* strains.

**Figure S3 (mBio02526-24-s0003.tif).** Comparison of HADA intensity profiles and HADA incorporation at the different poles for WT, *Msmeg\_ΔfhaA*, and *Msmeg\_ΔfhaA\_fhaA* strains.

**Legend (mBio02526-24-s0004.docx).** Video S1 legend.

**Supplemental Tables (mBio02526-24-s0005.xlsx).** Tables S1 to S5.

**Video S1 (mBio02526-24-s0006.mp4).** 3D reconstruction from virtual sections of a cell tomogram of a *Msmeg\_fhaA* cell with an altered cell topography at the cell poles.
